Highlights

The Wantou section (Guangxi province) S. China) had been previously studied for ammonoid, conodont and carbon-isotope stratigraphy (Galfetti et al., 2007, 2008) and the main events and trends are bracketed by a succession of a dozen volcanic ashes that have yielded ID-TIMS U-Pb ages (Ovtcharova et al., 2006, 2015). This new study added a detailed magnetostratigraphy and enhanced the conodont and stable isotope stratigraphy for high-resolution global correlation, plus replicated the main magneto-biostratigraphic events in an additional section at Youping. The combined results indicate that the Wantou section is an ideal candidate for the Early-Middle Triassic boundary stratotype. The preferred level for the Anisian GSSP is a horizon that records the first Chiosella timorensis s. str. conodont near the brief polarity chron MT1n.

Abstract—The Wantou and Youping sections of Guangxi, South China provide a detailed high-resolution integrated calibration of the Early-Middle Triassic boundary succession for lithostratigraphy, volcanic episodes, conodont first occurrences (FOs), ammonoid biostratigraphy, geomagnetic polarity, inorganic carbon isotopes, sea-surface temperatures derived from conodont-apatite oxygen-isotopes, and ID-TIMS U-Pb radiometric dating. The upper Spathian (late Early Triassic) magnetostratigraphy is characterized by normal polarity (magnetozone LT9n) that encompasses the FOs of the typical Spathian conodonts Triassopathodus homeri and Gladigondolella carinata, the late Spathian Neopanoceras haugi ammonoid zone and the beginning of a progressive positive shift in inorganic carbon isotopes. The overlying reversed polarity interval (LT9r) contains two brief normal-polarity subzones (MT1n and MT2n) that can be recognized in several other marine and terrestrial sections. The FO of conodont Chiosella timorensis sensu stricto, a proposed base-Anisian global marker, is near MT1n and near the end of the positive $\delta^{13}$C$_{carb}$ excursion. Sea-surface temperatures were reported to have cooled by 4°C during this rise in $\delta^{13}$C$_{carb}$, suggesting a sequestration of carbon dioxide. The lowermost Anisian at Wantou and Youping is dominated by normal polarity (MT3n, with the presence of one major reversed-polarity subzone MT3n.1r), contains the FO of typical Anisian conodonts (Gladigondolella tethydis/Magnigondolella alexanderi), and has the onset of a plateau in inorganic carbon isotopes values (stabilizing around +4%). The combination of the FO of conodont Chiosella timorensis s. str., the brief normal polarity zone (MT1n) and the last portion of the rising carbon-isotope trend are suitable for primary proxies for global correlation of the Early-Middle Triassic boundary (base of Anisian) to other marine and non-marine settings. Radiometric dates at the Wantou and at the Guandao sections, coupled with a composite cyclostratigraphy for Early Triassic through Anisian, indicate that the FO of the conodont Chiosella timorensis s. str. is at approximately 246.7 Ma.

Additional details and figures

The Wantou section (24.5915°N, 106.8625°E) at Jinya, Fengshan County, Guangxi province, South China, and the Youping section (24.9583°N, 206.5391°E), about 52 km northwest of the Wantou section (Fig. 1), have a similar lithological conformable succession of thick-bedded limestone with abundant bioclasts (Unit V of the Luolou Fm), transition beds of thin-bedded, siliceous mudstone containing calcareous nodules and the basal Baifeng Fm with laminated shale (Figs. 2 and 3). This succession is punctuated by a series of fine- and coarse-grained volcanic ash layers, of which the thickest are known informally as the “Green Bean Rock”, that have yielded precise radiometric ages.

The conodont biostratigraphy at Wantou in this study embraced the Early-Middle Triassic boundary conodont faunal turnover from previous studies, which is the complete replacement of late Spathian assemblages of Triassopathodus, Spathicuspus and Novispathodus by basal Anisian fauna of Gladigondolella, Chiosella and Neogondolella (Magnigondolella). There are five conodont appearance events identified as expedient in constraining the boundary interval in the Wantou and on a global scale. They are, in ascending order: FO of Tr. homeri/T. ex gr. homeri; FO of Gl. carinata; FO of Ch. timorensis s. str.; FO of Gl. tethydis; and FO of Magnigondolella alexanderi/Ng. ex gr. regalis (Fig. 2).

The Wantou section is dominated by normal polarity, with one significant reversed-polarity zone spanning the EMIB interval and another at the top (WT2r). The overall generalized polarity pattern is consistent with the cycle-tuned geomagnetic polarity time scale (GPTS) for the Early-Middle Triassic (Hounslow and Muttoni, 2010; Li et al., 2016, 2018; Ogg et al., 2016). Based on the conodont distribution and inorganic carbon isotope trends, polarity zone WM1n is equivalent to LT9n of Hounslow and Muttoni (2010), subzone WT1r.4n as MT1n, WT1r.7n as MT2n, and WT2n as MT3n (Fig. 2). The WT1r (EMIB interval) contains multiple normal-polarity subzones, of which two (WT1r.4n, WT1r.7n) are documented by multiple paleomagnetic samples and are considered coeval with MT1n and MT2n of Hounslow and Muttoni (2010) with global correlation potential (Fig. 2).
The late Spathian positive carbon isotope shift followed by an early Anisian plateau has been documented at Losar, North India (Galfetti et al., 2007), Deşli Caira, Romania (Grădinaru et al., 2007), Guandao, South China (Lehrmann et al., 2015) and at Wantou (Ovtcharova et al., 2015; and this study). The beginning of the $^{13}C_{\text{carb}}$ plateau is near the base of polarity zone WT2n (= chron MT3n of Hounslow and Muttoni, 2010) (Fig. 2) and slightly above the FO of Ch. timorensis s.str. at Guandao, Wantou and Deşli Caira.

The combination of potential global isochronous markers includes magnetic polarity chron, conodont occurrences (the FO of Ch. timorensis s.str., the preferred potential proxy in this study for the Anisian GSSP level, is at about 20% up within the reversed-polarity subchron MT1r between the brief MT1n and MT2n), typical ammonoid occurrences (the FO of Ch. timorensis s.str. level is 1.3 m above the last occurrence of Neopopanoceras bangi), carbon isotopes (the FO of Ch. timorensis s.str. level is 0.74 m below the peak of a significant positive excursion) (Fig. 2), and an age model from the combination of U-Pb dates with regional cyclostratigraphy (the FO of Ch. timorensis s.str. is projected to be at approximately 246.7 Ma).

This combination implies that the Wantou outcrops of Guangxi, South China, have great potential as the GSSP reference section for the Early-Middle Triassic boundary and can enable precise global correlation into different facies.

A formal GSSP proposal is being prepared by this group in coordination with the other teams that have studied this section, and a potential Anisian working-group field meeting is being planned for May-June of 2020 in association with a Geobiology Congress in Wuhan, China.
